## Chapter 1

## Approximation Methods

## 1.1 Linear Approximation

By using the slope at point (a, b), we're estimating the value f(x) where x is near a:

$$L(x) = y = f(a) + f'(a)(x - a)$$

### 1.2 Bisection Method

By taking advantage of the Intermediate Value Theorem, which states that if f(a) < 0 and f(b) > 0 and f(x) is a continuous function, then there must exist a  $c \in [a, b]$  such that f(c) = 0.

The idea is to use 2 points, bisect the interval into 2 intervals and check which one contains the root i.e. which one has a positive and a negative output.

### 1.3 Newton's Method

If we can't solve f(x) = 0, then we can replace f(x) with a linear approximation L(x) and solve equation L(x) = 0 instead. This can be illustrated as an iterative formula which is described as:

The Linear Approximation: 
$$L_{x_n}(x) = f(x_0) + f'(x_0)(x - x_0)$$
  
The Iterative Formula:  $x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)}$ 

### 1.4 Fixed-Point Iteration

Theorem: Convergence of Fixed-Point Iteration Suppose that f(x) is defined for all  $x \in \mathbb{R}$ , that it is differentiable everywhere, and that its derivative is always bounded(so that there are no points with vertical tangents). If the equation f(x) = x has a solution(i.e. if f(x) has a fixed point), and if |f'(x)| < 1 for all values of x within some interval containing the fixed point, then the sequence generated by letting  $x_{n+1} = f(x_n)$  will converge, with any choice of  $x_0$ .

## Chapter 2

## **Polynomials**

## 2.1 Polynomial Interpolation

#### 2.1.1 Problem

Suppose we are given n+1 points and we would like to find a smooth curve which passes through all of them. The simplest such curve which passes through all of them of degree n.

#### 2.1.2 Steps

- 1. Let's say there are n+1 points. We define the polynomial as  $f(x) = a_n x^n + a_{n-1} x^{n-1} + \cdots + a_1 x + a_0$
- 2. Plug in each point into this polynomial and obtain n functions.
- 3. Incrementally find the difference between i and i+1, where  $\delta y_i = y_{i+1} y_i$ . As a result, this reduces the amount of variables in the polynomial
- 4. After isolating the first coefficient, it becomes simple to isolate each other coefficients using the derived equations.
- 5. We can then plug these coefficients into the original polynomial and obtain a result.

OR you can use a general formula:  $y = y_0 + x\Delta y_0 + x(x-1)\frac{\delta^2 y_0}{2!} + \dots + x(x-1)(x-2)\dots(x-n+1)\frac{\Delta^n y_0}{n!}$ 

Side Note: If each node is equidistant, then there's a simpler generalization:  $y = y_0 + \frac{x - x_0}{h} \Delta y_0 + \frac{(x - x_0)(x - x_1)}{2!h^2} \Delta^2 y_0 + \dots + \frac{(x - x_0)(x - x_1) \dots (x - x_{n-1})}{n!h^n} \Delta^n y_0$ 

## 2.2 Taylor Polynomials

#### 2.2.1 Idea

The idea behind this is to use the secant line in the Linear Approximation and using Polynomial Interpolation to derive a polynomial that is similar to a function's shape due to its derivatives. By reaching the  $n^{th}$  derivative where n gets

bigger and bigger, the polynomial resembles more and more to the function.

tl;dr: 
$$P_{n,x_0}(x) = \sum_{k=0}^n \frac{f^{(x)}(x_0)}{k!} (x-x_0)^k$$

tl;dr:  $P_{n,x_0}(x) = \sum_{k=0}^n \frac{f^{(x)}(x_0)}{k!} (x-x_0)^k$ This becomes really handy when you need to do complicated stuff on functions such as integrals since polynomials are easy to integrate.

#### 2.2.2Remainder Theorem

Suppose that f has n+1 derivatives at  $x_0$ . Then

$$f(x) = \sum_{k=0}^{n} \frac{f^{(k)}(x_0)}{k!} (x - x_0)^k + R_n(x)$$

where

$$R_n(x) = \int_{x_0}^x \frac{(x-t)^n}{n!} f^{(n+1)}(t) dt$$

 $R_n(x) = \int_{x_0}^x \frac{(x-t)^n}{n!} f^{(n+1)}(t) dt$ By applying some mathemagic on this, we obtain Taylor's Inequality:

The error in using the  $n^{th}$ -order polynomial  $P_{n,x_0}(x)$  as an approximation to f(x)satisfies the inequality

$$|R_n(x)| \le K \frac{|x-x_0|^{n+1}}{(n+1)!}$$

where  $|f^{n+1}(t)| \leq K$  for all values of t between  $x_0$  and x This allows us to find the error margin of the Taylor Polynomial when estimating values.
